ABSTRACT

The challenges posed by the Internet of Things (IoT) render existing security measures ineffective against emerging networks and devices. These challenges include heterogeneity, operation in open environments, and scalability. In this paper, we propose SST (Secure Swarm Toolkit), an open-source toolkit for construction and deployment of an authorization service infrastructure for the IoT. The infrastructure uses distributed local authorization entities, which provide authorization services that can address heterogeneous security requirements and resource constraints in the IoT. The authorization services can be accessed by network entities through software interfaces provided by SST, called accessors. The accessors enable IoT developers to readily integrate their devices with authorization services without needing to manage cryptographic keys and operations. To rigorously show that SST provides necessary security guarantees, we have performed a formal security analysis using an automated verification tool. In addition, we demonstrate the scalability of our approach with a mathematical analysis, as well as experiments to evaluate security overhead of network entities under different security profiles supported by SST.

1 INTRODUCTION

As recognized by many researchers including [36], the main challenges in security of the Internet of Things (IoT) include heterogeneity, operation in an open environment, and scalability. These challenges render existing security measures ineffective against emerging IoT networks and devices.

The networked entities in the IoT are heterogeneous in terms of both security requirements and resource availability. For example, safety-critical systems such as electric power grid, autonomous vehicles, or drones will require the strongest possible guarantees for authorization and authentication. For mobile payment applications such as Apple Pay, high performance may be desirable in addition to confidentiality and authentication of transactions. However, for battery-powered devices such as temperature sensors, the lifetime and availability are considered just as important as data security. For some sensors, guaranteeing data integrity can be enough; it may not be necessary to keep sensor data confidential.

Insisting on maximum security for all devices in the IoT is not practical. To the best of our knowledge, there has not been a single integrated security solution for the IoT that supports heterogeneous requirements from safety-critical systems to sensor nodes. Existing, widely used security measures including SSL/TLS (Secure Socket Layer/Transport Layer Security), Kerberos, and various solutions for WSN (Wireless Sensor Network) and MANET (Mobile Ad hoc Network) are designed for homogeneous networks, and may not be directly applicable in a heterogeneous IoT setting. For instance, an approach purely based on SSL/TLS would be too prohibitive in an IoT network, due to the high computational requirements of public-key cryptography operations.

Another challenge arises due to risks involved with operating safety-critical components in open, untrusted, and even hostile environments. The threat model for existing, web-connected networks is reasonably well-understood, with a variety of mitigations developed to guard against potential attacks. Due to its open nature, however, an IoT network is susceptible to entirely new classes of attacks, which may include illegitimate access through mediums other than traditional networks (e.g., physical access, Bluetooth, radios). For instance, Ghena et al. [14] demonstrate an attack on a traffic controller on the streets of Ann Arbor, Michigan, including manipulation of actual traffic lights; this attack was made possible via direct radio communication with the traffic controller. Thus, the security solution for the IoT should provide ways to mitigate the potential effect of compromised entities in an open environment.
The final challenge is scalability of connected devices in the IoT. Many reports on scalability of the IoT, including one by Cisco [9], expect there will be tens of billions of connected devices by 2020, far exceeding the world population. Hence, the security solution must scale accordingly; in particular, the overhead of adding and removing devices to/from the security solution should be minimal.

To address these challenges, we propose SST (Secure Swarm Toolkit), a toolkit for building an authorization service infrastructure for the IoT. The key features of our approach include:

- We propose an open-source implementation of a local authorization entity, Auth, that can be downloaded and deployed by anyone with moderate knowledge of computer security. Auth can be deployed on smart gateways including Intel’s IoT gateways\(^1\) and SwarmBox\(^2\) from the TerraSwarm project,\(^3\) to authenticate and authorize IoT devices and establish secure connections.
- Auth provides a variety of security alternatives depending on security requirements and resource availability. These alternatives range from strong and frequent authorization for safety-critical components to lightweight message integrity guarantees for resource-constrained sensor nodes.
- The proposed Auth has control over existing connections among the IoT devices, providing mechanisms to mitigate damage caused by compromised or subverted entities, by revoking credentials of compromised entities.
- Our infrastructure includes actor-based software components that are designed to help non-security expert developers design secure software for the IoT. This is achieved by enforcing a secure implementation and composition of software through actor-based programming semantics.
- To rigorously show that SST provides necessary security guarantees, we have performed a formal analysis on a model of our authorization protocol using an automated verification tool. As far as we know, this is the first security framework for the IoT that has been subjected to a rigorous, formal security analysis.

2 MOTIVATION

In this section, we discuss why current state-of-the-art network security solutions cannot address some of the IoT security challenges, and why an integrated security framework is needed. We summarize the main challenges as follows.

1. **Heterogeneity**: Diversity in security requirements and resource availability (including devices with resource constraints and/or intermittent connectivity).

2. **Open environment**: Increased risks of operation in an environment where adversaries have physical and/or wireless access to IoT devices.

3. **Scalability**: A large number of devices and a high volume of communication traffic including one-to-many traffic patterns such as broadcasting or publish-subscribe.

For our discussion, consider data collection in WSN (wireless sensor network) using a UAV (unmanned aerial vehicle), as shown in Figure 1. This example is motivated by Shih et al. [35]

3 PROPOSED APPROACH OVERVIEW

In this section, we show an overview of SST, and discuss how it addresses the main challenges stated in Section 2.

3.1 Open-source Local Authorization Entity, Auth

Figure 2 illustrates the network architecture for the SST infrastructure based on local authorization entities, Auths [20]. An Auth is a program to be deployed on edge devices [13] including smart gateways, responsible for authentication/authorization of locally registered entities. An open-source implementation of Auth is available on our GitHub repository. Compared to the conceptual prototype in [20], our new implementation is written in a memory-safe language (Java), supports connectionless protocols such as UDP, provides more security configurations, and uses a full-fledged database, SQLite, with all credentials encrypted.

3.2 Software Components for Accessing Authorization Service

We also propose actor-based software components for accessing the authorization service called Secure Communication Accessors shown in Figure 3. Accessors² [21] are actors [22] [16] specialized for accessing remote services to enable composition of heterogeneous devices and services in the IoT. The interaction of accessors is orchestrated by the actor model, allowing concurrent execution, segregation of private data and message passing. A secure communication accessor internally manages its credentials (cryptographic keys), and uses the keys for encryption, decryption, and message authentication. Thus, an accessor liberates application developers from the need to manage cryptographic keys and operations, while providing security guarantees for accessing remote services.

3.3 How the SST Infrastructure Works

Communications between the IoT entities in our infrastructure are protected by symmetric cryptographic keys, called session keys. These keys are generated by Auth and distributed only to entities that are authorized for access/communication. For secure delivery of session keys, Auth and an entity share another symmetric key called distribution key. Figure 4 illustrates the process of establishing a secure connection between Client and Server. Both Client and Server are registered with Auth, and employ SecureCommClient and SecureCommServer accessors, respectively, for secure communication with Auth and with each other. Details on accessors are found in Section 4.6.

To build a secure connection, Client and Server must obtain a session key from Auth. In step (1) of Figure 4, Client receives a session key from Auth, encrypted with the distribution key between Client and Auth. Through step (2), Server receives the same session key encrypted with the distribution key between Server and Auth. Details of (1) and (2) are described in Section 4.3. To prove the ownership of the session key to each other, Client and Server perform a challenge-response handshake using nonces (random values) in step (3). After step (3) succeeds, they can start a secure communication as in step (4). Details of (3) and (4) are explained in Section 4.4.

3.4 How the Proposed Approach Addresses Challenges

3.4.1 Heterogeneity. SST supports various security configurations, which can be used to achieve tradeoffs between security guarantees and resource usage. Figure 5 depicts the space of configuration options. This space includes multiple alternatives for key distribution (D-1, D-2, D-3), cryptography strength and key lifetimes (C-1, C-2, C-3), session key usage (S-1, S-2, S-3), the number of session key owners (O-1, O-2, O-3), cached session keys (K-1, K-2, K-3), and reliability of the underlying protocol (P-1, P-2). An example of cryptography strengths is AES ciphers with different key sizes.

3.4.2 Open environment. Auth is a central point of authorization, keeping track of credentials and authorization requests. Thus, Auth can revoke credentials of compromised entities to limit their potential damage. This is important for devices operating under a high risk of being compromised due to the physical or wireless access by potential adversaries. For attack detection, various IDSs (Intrusion Detection Systems) [7] can be deployed in combination with Auth, leveraging the fact that all traffic relevant to authorization is directed through Auth.

3.4.3 Scalability. The scalability problem is twofold: (1) how to handle a large number of entities and (2) how to handle increased data traffic. Our approach addresses the first problem by allowing multiple Auths to be deployed in a network. To show how this works, we use a simple operation example described in Figure 6, where Client and Server are registered with two different Auths, Auth1 and Auth2, respectively. For Client and Server, the overhead for establishing a secure connection is no more than it would be with a single Auth, since they only need to communicate with their own Auth at all times. Auth1 and Auth2 still need to communicate with each other to deliver the same session key to Client and Server, but this exchange needs to occur only once before Client and Server can communicate without additional overhead. An analysis in Section 6 shows our approach’s scalability.

To handle increased data traffic, our infrastructure supports shared session keys for one-to-many communication patterns. Figure 7 describes an example of secure publish-subscribe communication in SST. For Publisher and Subscriber programs, we use corresponding accessors, SecurePublisher and SecureSubscriber. Publisher and two Subscribers, Subscriber1 and Subscriber2, are first registered with Auth. They are also connected with a possibly untrusted message broker which forwards published messages to subscribers. Publisher and two Subscribers are authorized by Auth, and each receives the same session key to be used for published messages. Publisher only needs to encrypt the message and send it once even when the number of Subscribers increases. This process is further explained in Section 4.4 and evaluated in Section 7.2.

4 DESIGN AND IMPLEMENTATION

In this section, we describe the design and implementation of SST, including the local authorization entity, communication protocols, and accessors.

4.1 Local Authorization Entity, Auth

Auth’s role is to authenticate and authorize locally registered entities. It also interacts with other Auths to allow communication between entities on different networks. Auth makes its authorization decisions based on a database of access policies and configurations, as shown in Figure 8. The database includes:

- **Registered entity table**: Stores information about entities registered with the Auth, including its credentials (cryptographic keys) and the configuration related to key distribution (details in Section 4.3).
- **Communication policy table**: Stores access policies between entities (for example, which entity can talk to which entity, what kind of cryptography should be used, and how long the cryptographic keys should be valid).
- **Cached session key table**: Stores cached session keys, which Auth allows for entities with limited connectivity. Each session key is associated with its owners and the max possible number of owners (two for server/client, and three or more for one-to-many communication).
- **Trusted Auth table**: Stores information and credentials for other trusted Auths, including each Auth’s unique ID, network address, port, and certificate.
whether the distribution key is to be updated or not:

If a distribution key is compromised, session keys encrypted with the distribution key.

8 Generation of credentials (cryptographic keys) can be done using tools such as OpenSSL command line tools.

9 This is becoming more common for IoT devices that need credentials for cryptography operations.

5 The distribution key is important because it is used for encrypting session keys. If a distribution key is compromised, session keys encrypted with the distribution key can also be compromised. Updating distribution keys can mitigate the effect of a compromised distribution key.

4.2 Entity Registration

Each entity must be registered with Auth in order to access the authorization infrastructure. The main purpose of this registration process is to set up credentials between Auth and an entity. An entity’s credentials may be generated during the registration or shipped by the manufacturer with the entity.

If an entity is capable of performing public-key cryptography operations to update its distribution key (explained in Section 3.3), the entity and Auth must exchange their public keys. If an entity cannot perform public-key cryptography, then the entity and Auth can set up a permanent distribution key. In addition to setting up the credentials, the entity’s unique name, security configurations, and communication policies are also set up during entity registration.

If a severely resource-constrained entity cannot directly connect to Auth or perform symmetric-key decryption, the entity will not be able to obtain any session key from Auth. However, even such an entity can be part of the infrastructure if it has preloaded session keys. In this case, the entity’s preloaded keys are stored in Auth during entity registration.

4.3 Auth – Entity Communication

Auth authorizes entities to communicate with each other by distributing a session key shared by entities. Figure 9 shows the authorization process, which starts with step (1) CONNECT_TO_AUTH. If an entity uses TCP, step (1) is TCP connection establishment with Auth. If the entity uses a connectionless protocol such as UDP, step (1) is entity’s ENTITY_Hello message, which simply triggers step (2). After step (1), Auth sends (2) AUTH_HELLO message, which includes Auth’s ID and its fresh random nonce, N_auth.

Step (3) SESSION_KEY_REQUEST must include N_entity, N_entity (entity’s random nonce), the name of the requesting entity, the purpose of the request (e.g., for communication with an entity in a certain group or a certain publish-subscribe topic), and the number of keys requested. N_entity is to ensure step (4) is not replayed. (3) must be at least authenticated, and can be optionally encrypted as well for confidentiality. There are two cases of (3) depending on whether the distribution key is to be updated or not:

- If the entity already has a valid distribution key, the message authentication (and optionally, encryption) must be done using the distribution key.
- If the entity does not have a valid distribution key or wants to update it using public-key cryptography, (3) must be authenticated with the entity’s private key, and optionally encrypted with Auth’s public key.

Given that the message in (3) is valid, Auth consults its communication policy table and determines whether the requesting entity should be authorized. If so, it generates new session keys or fetches existing, cached keys to be returned to the requesting entity; in addition, if necessary, it also generates a new distribution key.

In (4), Auth sends back SESSION_KEY_RESPONSE, which includes N_entity, new session keys, a security specification for the session keys, as well as a new distribution key if requested in (3). This message must be authenticated and encrypted with the distribution key; when a new distribution key is sent, it must be encrypted with the entity’s public key and signed with Auth’s private key. After receiving (4), the entity decodes it to check the validity of N_entity and Auth’s MAC (Message Authentication Code) and/or signature. If the message is valid, the entity stores the received session keys (and if applicable, the updated distribution key).

To support UDP, a connectionless protocol, Auth maintains its responses until a specified timeout so that it can respond again in case any message is lost. If Auth detects anything wrong or suspicious such as use of an expired distribution key, it sends an AUTH_ALERT message to the entity.

4.4 Entity – Entity Communication

Auth authorizes entities to communicate with each other by distributing a session key shared by entities. Figure 10 describes two ways of secure communication provided by the SST infrastructure.

Figure 10 (a) shows a server-client type of secure communication. To first confirm the validity of each other’s session key, Server and Client carry out a simple challenge-response by performing cryptographic operations on random nonces in steps (1) to (3). This process is similar to PSK Key Exchange Algorithm of PSK cipher suites for TLS [11]. For identification of the session key, we use its unique identifier, session key ID. As part of its value, the session key ID also includes the ID of Auth who generated it, and thus it can be used to identify the generator. The session key ID is analogous to the PSK identity of PSK Key Exchange Algorithm of TLS.

Optionally, we can configure the session key to be used to authenticate an ephemeral Diffie-Hellman key exchange to derive a new session key in steps (2) to (3). This process is similar to DHE_PSK Key Exchange Algorithm of PSK TLS [11], which provides additional protection such as Perfect Forward Secrecy (PFS).
Having successfully performed the handshake, Server and Client can start a secure communication protected by the session key. Each CLIENT_MESSAGE or SERVER_MESSAGE includes a read/write sequence number that increases per message. These sequence numbers are used to detect whether a certain message is missing or replayed by attackers. The sequence numbers are similar to those in the application data record protocol of SSL/TLS. Our approach supports both TCP and UDP for this server–client communication.

Figure 10 (b) shows a publish-subscribe style of communication supported by SST. Publisher and Subscribers have the same session key to be used for messages. Publisher encrypts and/or authenticates a SECURE_PUBLISH message, attaches the session key ID in plaintext (so that Subscribers can identify which session key is used for the message), and sends it to the Message Broker, which in turn forwards the message to Subscribers. Only those Subscribers with a valid session key can decrypt and/or check authenticity of published messages. To mitigate risks where a compromised subscriber illegally publishes messages, SST supports delayed disclosure of keys using a technique similar to that of the TESLA protocol [28].

4.5 Auth – Auth Communication

Auth communicates with other Auths to request a session key that was generated by the other Auths. Trusted Auths are connected to each other over HTTPS on top of SSL/TLS, using POST request/response for communication. Figure 11 illustrates the steps of Auth – Auth communication. Entity, which is registered with Auth1, requests a session key that was generated by Auth2. This case can happen when Entity wants to set up a secure communication with another entity registered with Auth2. Auth1 receives SESSION_KEY_REQUEST that specifies the session key’s ID. As explained in Section 4.4, the session key ID includes the generator’s ID, in this case, Auth2’s ID. From this ID of Auth2, Auth1 discovers that the requested session key was generated by Auth2 and sends (1) AUTH_SESSION_KEY_REQUEST which includes Entity’s information, the purpose of the request, and the session key’s ID. Auth2 responds to Auth1 if the Auth1’s request is eligible with (2) AUTH_SESSION_KEY_RESPONSE which includes the requested session key and cryptography specification of the session key. Upon receiving (2), Auth1 responds to Entity.

4.6 Secure Communication Accessors

Accessors use a JavaScript file to specify interactions (inputs, outputs, and parameters) and functionality implementations (reaction to inputs and/or production of outputs). Many accessors use asynchronous atomic callbacks (AAC), for requesting remote services and handling following responses asynchronously and atomically.

For constructing a secure swarm applications, we provide four secure communication accessors for accessing authorization services, SecureCommClient, SecureCommServer, SecurePublisher, and SecureSubscriber as shown in Figure 12. In common, all these accessors manage a distribution key and cached session keys internally with parameters for security configurations and credentials. The proposed accessors provide standardized interfaces over different underlying implementations. Incoming and outgoing triangles on each accessor indicate input and output ports of the accessor, respectively. If any security condition is violated, these accessors generate an output on their err_output port. Detailed documents are available on our accessor library under net group.

SecureCommClient and SecureCommServer generate an output connection when a new secure connection is established. Both SecureCommClient and SecureCommServer send a secure message to the counterpart when there is an input on toSend and generate an output on received when a secure message arrives. toSendID and receivedID of SecureCommServer are used to specify a specific client since there can be multiple clients connected to the same server.

SecurePublisher and SecureSubscriber use a MQTT [5] message broker for publishing and subscribing secure messages. When they are connected to the broker, they generate an output on connected. If SecurePublisher obtained the session key and is ready to publish, it generates an output on ready. When there is an input on toPublish, SecurePublisher sends a secure publish message for the topic specified as a parameter. SecureSubscriber can subscribe and unsubscribe on a specific topic and an output on subscription indicates the subscription status. When a secure publish message arrives on the topic, outputs are generated on received and receivedTopic ports.

5 SECURITY ANALYSIS

In this section, we present a security analysis of our proposed authorization infrastructure. To make the analysis rigorous, we constructed a formal model of the Auth protocol, and applied an automated verification tool to exhaustively explore all possible behaviors of the model for vulnerabilities. 

5.1 Security Properties and Threat Model

The purpose of Auth is to provide a secure channel for trusted entities on an Auth network to communicate to each other, even in the presence of possibly malicious entities. To be more specific, in our analysis, we wish to establish the following two security properties: (1) Each message sent from an entity should be accessible to its intended recipient(s) (confidentiality of a message), and (2) A message delivered to an entity has the same content as it is sent.
by its source entity (data integrity and authenticity of a message). In our current threat model, we do not consider security guarantees against availability attacks, such as denial of service (DoS) or depletion of energy resources; this remains part of our future work.

We assume the presence of an active network attacker, who is able to eavesdrop on communication among network nodes, and potentially modify or replay any messages. We further allow the attacker to take on the role of an entity itself, interacting with Auths or other entities on the network. The attacker may have access to public keys of Auths and entities, their IDs and names, and impersonate another entity while interacting with an Auth. However, we assume that the attacker is not capable of impersonating Auth.

### 5.2 Formal Analysis

#### 5.2.1 Modeling Auth in Alloy

Alloy is a modeling language based on a first-order relational logic [18]. It has been used to analyze a wide range of systems, including web applications [1], network configurations [24], and security policies [25]. Alloy is a particularly suitable choice for specifying and analyzing IoT networks, thanks to (1) its expressiveness, which allows modeling of a dynamic network where its topology evolves as nodes enter and exit, (2) its type system (with a flexible subtyping mechanism), which allows modeling of heterogeneous components that share common characteristics, and (3) its analysis engine, which can perform simulation and verification of a model against various properties, such as safety, security, and functional correctness.

Figure 13 shows a snippet of a model of our authorization infrastructure in Alloy; due to limited space, a simplified version is shown here\(^\text{10}\). The model\(^\text{11}\) begins with declarations of datatypes that will be used for communication in an Auth network (lines 2-8). In particular, two types of Key are declared: SymKey, which represents symmetric keys that will be used as distribution and session keys, and AsymKey, each of which is associated with a corresponding asymmetric key (pair) that can be used for public-key cryptographic operations. A constraint is introduced to ensure that each asymmetric key is assigned a unique pair (line 8)\(^\text{12}\).

The set of Auth and entities in the world are collectively referred as Node in our model. Each node is assigned a pair of public and private keys that can be used for secure communication with other nodes in the network (line 10). Every Auth object is associated with an ID, and has access to a set of public keys that it uses to encrypt messages sent to entities (line 15). Similarly, each Entity is assigned a name, and knows the public keys of Auths that it communicates to (line 24). For our analysis, we will assume some subset of the entities to be malicious (line 29)\(^\text{13}\).

#### Modeling behavior

To reason about the dynamic behavior of a network, we use a style of modeling where an execution is modeled as a sequence of time steps, and each mutable object is associated with a state at each step [18]. In this model, we declare the signature Time to represent the set of time steps, and attach it as the last column of every relation that stores mutable records. For example, consider the field sessionKeys (line 17), which is a ternary relation of type Auth × SymKey × Time; tuple \((a, k, t)\) belonging to sessionKeys means that \(k\) is one of the session keys that Auth \(a\) has allocated for its entities at time \(t\).

Communication between two nodes is modeled using a set of objects called Message. Each message is associated with a sender and a receiver, and a time step \(t\) at which the message is sent.

---

\(^{10}\)The full model is available at https://github.com/intauth/security_analysis.

\(^{11}\)The Alloy keyword `sig` introduces a signature, which defines a set of elements in the universe. A signature may contain one or more fields, each introducing a relation that maps the elements of the signature to the field expression, for example, field name in Entity is a binary relation that maps each Entity object to its name (line 22). The keyword extends creates a subtyping relationship between two signatures; an abstract signature has no elements except those belonging to its extensions.

\(^{12}\)A fact is a constraint that must hold over every instance of the model.

\(^{13}\)The keyword `in` imposes a subset relationship between two sets.
and delivered. The sender and receiver behavior associated with each type of message is defined using signature constraints. For instance, consider \texttt{SESSION\_KEY\_REQUEST}, which corresponds to a set of messages that an entity sends to an Auth (with \texttt{id}) in order to request a session key for communicating to another entity (identified by \texttt{target}). Here, we only depict the case in which the sender does not possess a distribution key. The definition of \texttt{SESSION\_KEY\_REQUEST} requires that both the names of the sender and target entities are encrypted using the receiving Auth’s public key, and then signed with the sender’s private key (lines 35-36).

When Auth receives the message, it allocates a new symmetric key, \texttt{newKey}, and inserts it into its current list of session keys and their owners (lines 37-39). In response, Auth sends back a \texttt{SESSION\_KEY\_RESP} message with a distribution key and the newly generated session key. It encrypts the session key with the distribution key (line 45), which is, in turn, encrypted with the public key of the receiving entity to ensure its secrecy (lines 46). Having obtained the session key, the entity is now able to send a secure message (\texttt{SECURE\_MESSAGE}) to its target entity by encrypting the payload using the key (line 52).

5.2.2 Verification Procedure. The Alloy Analyzer is a tool that can be used to execute a model or automatically verify it against a desired property. The tool is capable of exhaustive, bounded verification; that is, it will explore all possible behaviors of the modeled system, up to certain upper bounds on the length of an execution trace and the number of system and data components. Verifying an infinite system is an undecidable problem in general [4], and so to render the analysis fully automatic, the tool makes a trade-off by asking the user to specify the bounds for the input model.

One of the security properties of Auth that we verified using the tool is shown in Figure 13 (lines 55-58). This confidentiality property says that there should never be a time \(t\) at which an attacker \(a\) is able to access one of the payloads \(s\) that belongs to a non-attacker entity \(e\). When executed with a check command, the analyzer will attempt to generate a counterexample (if it exists within the bounds) that demonstrates how the model violates the property. In this case, such a counterexample would show an execution where there is at least one time step \(t\) at which the attacker receives a message containing a payload \(s\) of the victim entity \(e\).

5.2.3 Results. We analyzed our model of Auth against the properties stated in Section 5.1: confidentiality, data integrity and authenticity of each message. We specified an upper bound of 5 for the size of each signature (at most 5 unique Node objects, etc.), except 10 for the number of time steps and messages, which allowed the analyzer to explore all possible traces up to length 10.

Figure 14 shows the average times taken by the analyzer to generate a counterexample for different trace lengths. Overall, the analysis time shows an exponential growth over the maximum length of a trace explored by the analyzer. This trend is not surprising, since as the maximum length of a trace is incremented, the number of all possible traces also increases exponentially. For example, consider the three types of messages in Figure 13; since every message contains multiple parameters, each of which takes on one of five possible values (given the general upper bound of 5 on each signature), the number of messages that may be sent at a particular time step is \((5^2 + 5^2 + 5^2) = 175\). Thus, given a maximum trace length of 10, the number of possible combinations of messages (i.e., number of traces potentially explored by the analyzer) is approximately \(175^{10} \approx 2.69 \times 10^{22}\).

The analyzer generated 17 counterexample traces during our analysis. We examined each of these traces and incrementally fixed the model to ensure that the attack scenario captured by the trace would no longer be allowed by the model. These traces did not point to a fundamental security flaw in the design of Auth itself, but were due to missing security assumptions in our model. An assumption is a condition that must hold in order for a protocol to satisfy its security properties. For example, an assumption may describe the initial knowledge of an attacker (e.g., it does not have access to an entity’s private key), configuration requirements (each trusted entity and Auth pair are configured with each other’s correct public key), or what each protocol agent is not allowed to do (Auth never reuses a distribution key when it responds to a new entity).

Our initial model of Auth omitted many of these assumptions, since they were implicit in our original, informal protocol description. These counterexamples nevertheless demonstrate possible attacks on implementations that do not satisfy one of these assumptions. The analysis process improved our understanding of Auth, and helped us come up with a precise specification that explicitly lists security assumptions that every Auth implementation must satisfy. We believe this is especially important, since many implementations of cryptographic protocols have suffered from attacks due to missing or violated assumptions [2].

5.3 Limitations

Our current threat model assumes that all Auths are trusted and cannot be controlled by an attacker. Possible consequences of a compromised Auth are significant: The attacker may be able to manipulate messages from and to entities, undermining the security of the local Auth network and possibly its neighbors. We plan to extend SST with a detection and recovery mechanism in the presence of a compromised Auth.

Due to the bounded nature of the verification technique used, it is possible that our analysis may have missed one or more attacks on Auth. In our experience with Alloy, however, often a small number of messages are sufficient to demonstrate a flaw in a system [3]. For example, the smallest counterexample that we found required

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure14}
\caption{Verification times on the Auth model.}
\end{figure}
only 4 messages to demonstrate a possible attack on Auth, and the longest one involved 8 messages. To further increase the confidence in its results, one may repeat the analysis with increasingly larger bounds. We believe that this is an acceptable trade-off to achieve automation and an ability to generate counterexamples, which greatly aided our understanding of Auth.

6 SCALABILITY ANALYSIS

In this section, we provide a mathematical analysis of the scalability of the SST infrastructure. Figure 15 shows an example where entities registered with one Auth are divided into entity groups with two Auths. Let \( n \) be the total number of entities, \( k \) be the number of Auths, and \( n/k \) be the number of entities registered with each Auth (given \( n \) is divisible by \( k \)). Let \( c_1 \) be Auth’s overhead for session key request and response for its entity, and let \( c_2 \) be each Auth’s overhead for session key request and response between two Auths. Although actual \( c_1 \) and \( c_2 \) vary depending on underlying cryptography and communication configurations, we assume that they are the worst-case upper bounds for all possible configurations.

We assume that each entity sets up a server/client-style secure communication with a constant number of entities (\( m \)). For each connection, Auth needs to authorize a pair of entities involved. When \( k = 1 \), there are \( m \times n \) secure connections; thus, the total overhead for Auth is

\[
t_1 = mn \times 2c_1
\]

(1)

Now consider the case where \( k \geq 2 \). Among \( m \) entities that some entity \( e \) wishes to communicate to, let \( p(0 \leq p \leq 1) \) be the proportion of the entities registered with the same Auth as \( e \) is. Then, \( pm \) entities are registered with the same Auth as \( e \) is, while \((1-p)m\) entities are registered with other Auths. Since each Auth has \( \frac{n}{k} \) registered entities, the overhead for authorizing connections between entities in a single Auth is

\[
\frac{pm}{k} \times \frac{n}{k} \times 2c_1
\]

(2)

In addition, there is overhead for authorization of the entities that communicate with entities outside the Auth. Since this overhead for each Auth is \((c_1 + c_2)\) as in Figure 15, the resulting overhead is

\[
(1-p)m \times \frac{n}{k} \times (c_1 + c_2)
\]

(3)

Summing (2) and (3), for \( k \geq 2 \), the total overhead for an individual Auth is

\[
t_k = pm \times \frac{n}{k} \times 2c_1 + (1-p)m \times \frac{n}{k} \times (c_1 + c_2)
\]

(4)

Now, let \( r = \frac{n}{k} \) be the ratio of \( n \) and \( k \). The ratio \( r \) can also be considered as the number of entities per Auth. Even when \( n \) increases, we can keep \( r \) constant by having linearly more Auths.

Then, equation (4) becomes

\[
t_k = pm \times r \times 2c_1 + (1-p)m \times r \times (c_1 + c_2)
\]

(5)

Then, we can make \( t_k \) (the overhead of each Auth) independent of \( n \), assuming that we add more Auths linearly to the number of entities. Hence, in theory, our infrastructure should be scalable for an increasing number of entities.

7 EXPERIMENTS AND RESULTS

To evaluate our approach, we demonstrate a range of tradeoffs between security guarantees and energy consumption for different configurations provided by SST. We performed experiments for both client-server and one-to-many styles of communication. During our experiments, we measured the overhead of entities in establishing secure connections and sending secure messages. For each experiment, we tested different security configurations and varying numbers of communicating entities. In addition, we compared our approach against SSL/TLS as a reference.

The entities for our experiments were built using secure communication accessories. To run these entities as a composition of accessories, a special type of application called an accessor host is needed; we used a Node.js host\(^{19}\), which is based on Node.js [38], a JavaScript runtime platform. Java 1.8 was used to run Auth. In addition, Auth and entities were deployed on a single host with different port numbers.

We measured (1) computational security overhead by logging cryptographic operations\(^{20}\) and (2) communicational overhead by capturing network packets using a packet sniffing tool\(^{21}\). For cryptography operations, we used RSA-2048 for public-key cryptography, AES-128-CBC for bulk encryption, and SHA-256 for message authentication. This specification is one of the TLS 1.2 cipher suites, TLS_RSA_WITH_AES_128_CBC_SHA256, which is the cipher suite we used for our experiments of TLS. We converted the measurements into energy consumption to estimate overall security overhead. For this conversion, we used the energy cost model used in [20] (shown in Table 2).

Table 2: Energy cost model used in [20] (energy numbers from [32] and [12])

<table>
<thead>
<tr>
<th>Operation</th>
<th>Energy cost</th>
</tr>
</thead>
<tbody>
<tr>
<td>RSA-2048</td>
<td>91.02 ( m ) per encrypt/decrypt operation</td>
</tr>
<tr>
<td>AES-128-CBC</td>
<td>4.41 ( m ) per decrypt/verify operation</td>
</tr>
<tr>
<td>SHA-256</td>
<td>0.19 ( \mu J ) per byte encrypted/decrypted</td>
</tr>
<tr>
<td>Send packet</td>
<td>454 ( \mu J ) + 1.9 ( \mu J \times ) packet size (bytes)</td>
</tr>
<tr>
<td>Receive packet</td>
<td>356 ( \mu J ) + 0.5 ( \mu J \times ) packet size (bytes)</td>
</tr>
</tbody>
</table>

\(^{21}\)WireShark, https://www.wireshark.org/
alternatives. For each entity, either only one cached key was allowed or there was no limit on the number of cached keys. For the network protocol, an entity was allowed to use either TCP or UDP. For distribution key management, an entity was given either a distribution key to be updated using public-key cryptography or a permanent distribution key. If an entity was a distribution key to be updated, we assumed that the entity did not have a distribution key in its initial deployment.

Figure 16 shows the estimated energy consumption of a client for establishing/closing secure connections with 16, 32, and 64 servers under different configurations. Figure 17 shows the results for a server with 16, 32, and 64 clients. We can see that SST uses far less energy for secure connections than TLS for both the client and server. This is mainly because of the overhead associated with public-key cryptography: it rapidly increases with the number of communicating entities in TLS, but remains constant in SST, which employs public-key cryptography only for communication with Auth. However, note that this does not necessarily mean our approach is always more desirable than TLS, since the latter provides different types of security guarantees.

From the results, we can also observe that the estimated energy consumption of SST ranges approximately an order of magnitude under different configurations. An entity can save energy on public-key cryptography by trading off upatability of the distribution key. An entity can save energy on network communication by using cached keys and/or UDP. TLS consumes more energy on SHA-256 MAC than SST does, since it needs to verify client and server certificates, although there is only negligible difference in energy used for AES (symmetric cryptography) on data encryption/decryption.

### 7.2 A Sender and Multiple Receivers

In this section, we describe the security overheads in one-to-many communication architecture, where one node sends encrypted messages to multiple other entities. We conducted experiments with four different settings for a sender and receivers described in Figure 18. The first setting in Figure 18 (a) employed a separate, individual TLS connection between the sender and each receiver. Figure 18 (b) shows another setting using individual secure connections but with a shared session key distributed by Auth. The setting in Figure 18 (c) used a publish-subscribe protocol, MQTT [5], to connect the sender and receivers sharing a single session key. We used an open-source MQTT message broker [22] for forwarding published messages from the sender to receivers. We assumed that the broker should not be able to decrypt the published messages.

In the final setting shown in Figure 18 (d), we assumed that the sender and receivers were on the same local network; here, the sender employed a UDP broadcast for sending messages encrypted with a shared session key. An example of this last setting is one where messages are made broadly available to the local network, such as alerts or notifications. In addition, we varied the distribution key management for each experiment (i.e., updated or permanent distribution keys).

Figure 19 shows the estimated energy consumed for setting up keys and connections with different numbers of receivers. The energy consumption for TLS (Figure 18 (a)) and ISC (Individual Secure Connections, Figure 18 (b)) increases as the number of receivers increased. However, the energy consumption for MB (Message Broker, Figure 18 (c)) and UB (via UDP Broadcast, Figure 18 (d)) remains constant. This is because the sender in MB only needs to communicate with Auth and the broker, and the only overhead for the sender in UB occurs when obtaining a shared session key from Auth. The overhead of public-key cryptography occurs at most once in SST, resulting in less energy consumption than TLS as explained in Section 7.1.

---

22Mosquito (http://mosquito.org)
Assume that one uses ISC (193.5 mJ/message) while the other uses TLS because the sender in ISC only needs to encrypt the message once, thanks to the shared session key. However, the impact of this key operations, or share symmetric keys with other trusted devices prior to the deployment. Furthermore, CoAP is mainly designed for one-to-one communication (e.g., a client-server model), and does not directly support one-to-many settings (e.g., publish-subscribe).

A variety of security frameworks for sensor networks have been proposed and studied [6, 19, 23, 29, 30]. Sensors and IoT devices have similar resource constraints, but we expect the latter group to be more diverse in terms of the types of applications that they implement. SST can be deployed as an underlying infrastructure for a mixture of traditional sensor nodes as well as entities with application-specific requirements.

Wei et al. [39] propose a conceptual design of security infrastructure for deploying smart grid networks. Although their focus is on power grids, their approach is similar to ours in that it provides integration between different types of devices with varying performance and security requirements.

SHAWK [8] provides a secure mechanism of integrating heterogeneous wireless networks including cellular and WLANs. Like SST, SHAWK addresses heterogeneity by integrating existing solutions but at a different layer of abstraction.

To the best of our knowledge, SST is the first working implementation of an Internet-scale authorization infrastructure that covers heterogeneous security requirements from sensor nodes to safety-critical components, with an automated, formal security analysis. The proposed infrastructure is not just a protocol or key management system but it also provides standardized software components, accessors, for secure composition of IoT applications.

8 RELATED WORK

The most significant improvements of SST compared to our previous work [20] are the newly proposed accessors, a rigorous, formal security analysis and scalability analysis, and more in-depth experiments comparing a variety of security configurations. Other improvements include support for more alternatives such as UDP and Diffie-Hellman key exchange, and more concrete open-source implementation of Auth using Java and relational database, SQLite, with encrypted credentials.

OpenIoT [37] is a platform designed to enable integration among a collection of heterogeneous IoT applications. The platform leverages a publish-subscribe architecture to allow different types of devices to communicate to each other. For privacy and security, OpenIoT relies on a central authentication mechanism based on SSL, which, as we have discussed, is likely to face scalability challenges in dynamic IoT networks.

Hummen et al. [17] propose a security framework for IoT devices based on the datagram TLS (DTLS) protocol [31]. Similar to our approach, their framework employs specialized authorization entities, delegation servers, to reduce the amount of public-key cryptography computations. In comparison, SST provides a wider range of configurations, as shown in Figure 5, allowing each entity to create its own profile based on its security and resource requirements.

Seitz et al. [33] outline a set of desirable security and performance requirements for an IoT network, and propose a conceptual framework for controlling access to device resources using the XACML policy language [15]. However, their approach is not based on a particular authentication scheme, and does not directly address scalability issues.

The Constrained Application Protocol (CoAP) [34] is designed to support the types of low-power devices that are common on an IoT network. Communication between CoAP devices is secured using DTLS, which still relies on each individual device to perform public-key operations, or share symmetric keys with other trusted devices prior to the deployment. Furthermore, CoAP is mainly designed for one-to-one communication (e.g., a client-server model), and does not directly support one-to-many settings (e.g., publish-subscribe).

Figure 20 depicts the estimated energy consumption for a scenario where the sender attempts to deliver a 1 KB message to different numbers of receivers. The results show that the sender in MB and UB uses a constant amount of energy even when the number of receivers increases; this is because the sender only needs to encrypt and send the message once to the broker in MB and to the local network in UB. The sender uses less energy in ISC than TLS because the sender in ISC only needs to encrypt the message once, thanks to the shared session key. However, the impact of this is not significant because energy consumption in communication is dominant, and both TLS and ISC require sending messages to individual receivers separately. There is no difference between two distribution key management alternatives in this experiment because no public-key cryptography was used. To illustrate how different security configurations affect the lifetime of IoT devices, let us consider two battery-powered sensor nodes, each sending a 1 KB message to 64 receivers every minute. Assume that one uses ISC (193.5 mJ/message) while the other uses UB (3.0 mJ/message), and sending 1 KB messages is the only activity for these two sensor nodes. If we use a 500 mAh battery operating on 1.5 V, the total energy budget will be 0.75 Wh, which is 2.7 kJ. Under these conditions, the sensor node using ISC will die within 10 days while the one using UB will last for 625 days.
9 CONCLUSIONS

In this paper, we present SST, a novel toolkit for constructing an authorization service infrastructure for the IoT. We expect heterogeneous IoT devices, ranging from sensor nodes to electric power grid control systems, can be integrated into the authorization infrastructure by virtue of SST’s diverse security alternatives. Auth’s scalability will enable Internet-scale deployment of the proposed infrastructure together with SST’s support for one-to-many communication to cope with increasing data traffic. We also envision SST can facilitate further integration in IoT network protocols, for example, by providing key distribution mechanisms for existing network protocols for the IoT such as CoAP over DTLS.

As future work, we plan to solve challenges that still need to be addressed for further security of the IoT. One of the most important challenges is defense and mitigation against denial-of-service attacks breaching availability. We speculate the distributed nature of Auths in SST can help enhancing the IoT’s availability. Ease of deployment of authorization services for the IoT is another important challenge. Accessors included in the open-source SST are expected to reduce the burden of IoT developers and increase accessibility to security solutions. Other remaining challenges include timely detecting malicious behavior in the IoT and providing guarantees for swarm applications running remotely on untrusted IoT platforms.
